# Infomax and maximum likelihood for blind source separation

Jean-François Cardoso

Abstract— Algorithms for the blind separation of sources can be derived from several different principles. This letter shows that the recently proposed infomax principle is equivalent to maximum likelihood.

#### INTRODUCTION.

Source separation consists in recovering a set of unobservable signals (sources) from a set of observed mixtures. In its simplest form, a  $n \times 1$  vector  $\mathbf{x}$  of observations (typically, the output of n sensors) is modeled as

$$\mathbf{x} = A_{\star}\mathbf{s} \tag{1}$$

where the 'mixing matrix'  $A_{\star}$  is invertible and the  $n \times 1$  vector  $\mathbf{s} = [s_1, \dots, s_n]^T$  has independent components: its probability density function (p.d.f.)  $r(\mathbf{s})$  factors as

$$r(\mathbf{s}) = \prod_{i=1,n} r_i(s_i) \tag{2}$$

where  $r_i(s_i)$  is the p.d.f. of  $s_i$ .<sup>1</sup> Based on these assumptions and on realizations of  $\mathbf{x}$ , the aim is to estimate matrix  $A_{\star}$  or, equivalently, to find a 'separating matrix' B such that

$$\mathbf{v} = B\mathbf{x} = BA_{+}\mathbf{s}$$

is an estimate of the source signals.

A guiding principle for source separation is to optimize a function  $\phi(B)$  called a *contrast* function which is a function of the distribution of  $\mathbf{y} = B\mathbf{x}$  (see Comon [4]). Based on the *infomax principle*, an apparently new contrast function has recently been derived by Bell and Sejnowski [1], attracting a lot of interest. In this letter, we exhibit the contrast function associated to the well established *maximum likelihood (ML) principle*. By this device, we show that, regarding source separation, infomax principle boils down to maximum likelihood (ML).

## I. Infomax.

According to Bell and Sejnowski, application of the infomax principle [1] to source separation consists in maximizing an output entropy.

$$\mathbf{s} \longrightarrow A_{\star} \qquad \mathbf{z} \longrightarrow \mathbf{g}(\mathbf{y}) \longrightarrow \mathbf{z} = \mathbf{g}(\mathbf{y})$$

Plain maximization would be inappropriate because the entropy of  $\mathbf{y} = B\mathbf{x}$  diverges to infinity for an arbitrarily

The author is with the CNRS (Centre national de la recherche scientifique) and ENST (École nationale supérieure des télécommunications. Paris) cardoso@sig.enst.fr

<sup>1</sup>Throughout this letter, p.d.f.'s are with respect to Lebesgue measure. All distributions are assumed continuous with respect to it.

large separating system B. Thus, the infomax principle is implemented by maximizing with respect to B the entropy of  $\mathbf{z} = \mathbf{g}(\mathbf{y}) = \mathbf{g}(B\mathbf{x})$  where

$$[\mathbf{g}(\mathbf{y})]_i = g_i(y_i) \quad 1 \le i \le n.$$

is a  $\mathbb{R}^n \to \mathbb{R}^n$  component-wise non-linear function. Thus, the infomax contrast function is:

$$\phi_I(B) \stackrel{\text{def}}{=} H(\mathbf{g}(B\mathbf{x})) \tag{3}$$

where  $H(\cdot)$  is the (Shannon) differential entropy (11). Scalar functions  $g_1, \ldots, g_n$  are taken to be 'squashing functions', mapping the real line to the interval (0,1) and monotonously increasing. Thus, if  $g_i$  is differentiable, it is the cumulative distribution function (c.d.f) of some p.d.f.  $q_i$  on the real line:

$$q_i(s) = \frac{dg_i(s)}{ds}$$
  $g_i(s) = \int_{-\infty}^s q_i(y) \ dy.$ 

Denote  $\tilde{\mathbf{s}} = [\tilde{s}_1, \dots, \tilde{s}_n]^T$  an  $n \times 1$  random vector with p.d.f.:

$$q(\tilde{\mathbf{s}}) = \prod_{i=1}^{n} q_i(\tilde{\mathbf{s}}_i). \tag{4}$$

Then,  $g_i(\tilde{s}_i)$  is distributed uniformly on (0,1) since  $g_i$  is the c.d.f. of  $q_i$ . Thus,  $\mathbf{u} \stackrel{\text{def}}{=} \mathbf{g}(\tilde{\mathbf{s}})$  is distributed uniformly on  $(0,1)^n$  and the infomax contrast is rewritten as

$$\phi_I(B) = -K(\mathbf{g}(B\mathbf{x}) \parallel \mathbf{u}) = -K(B\mathbf{x} \parallel \tilde{\mathbf{s}}). \tag{5}$$

where  $K(\cdot||\cdot)$  denotes the Kullback-Leibler (KL) divergence (12). The first equality is the combination of (3) and (14); the second results from (13). It shows that 'infomaximization' is identical to minimization of the KL divergence between the distribution of the output vector  $\mathbf{y} = B\mathbf{x}$  and the distribution (4) of  $\tilde{\mathbf{s}}$ .

# II. MAXIMUM LIKELIHOOD.

We first recall how the maximum likelihood principle is associated with a contrast function. This is then specialized to the source separation model.

Consider a sample of T independent realizations  $\mathbf{x}_1, \ldots, \mathbf{x}_T$  of a random variable  $\mathbf{x}$  distributed according to a common density  $p_{\mathbf{x}}(\mathbf{x})$ . Let  $\mathcal{P} = \{p_{\theta}(\mathbf{x}) \mid \theta \in \Theta\}$  be a parametric model for the density of  $\mathbf{x}$ . The likelihood that the sample is drawn with a particular distribution  $p_{\theta}$  is the product  $\prod_{t=1}^T p_{\theta}(\mathbf{x}_t)$ . Taking the logarithm and dividing by the number of observations results in the normalized log-likelihood:

$$L_T(\theta) \stackrel{\text{def}}{=} \frac{1}{T} \log \prod_{t=1,T} p_{\theta}(\mathbf{x}_t) = \frac{1}{T} \sum_{t=1,T} \log p_{\theta}(\mathbf{x}_t).$$

Since this is the sample average of  $\log p_{\theta}(\mathbf{x})$ , it converges in probability, by the law of large numbers, to its expectation:

$$L_T(\theta) \stackrel{\mathcal{P}}{\to} L(\theta) \stackrel{\text{def}}{=} \mathrm{E} L_T(\theta) = \int p_{\star}(\mathbf{x}) \log p_{\theta}(\mathbf{x}) d\mathbf{x}.$$

Setting  $p_{\theta}(\mathbf{x}) = \frac{p_{\theta}(\mathbf{X})}{p_{\star}(\mathbf{X})} p_{\star}(\mathbf{x})$  in the above yields

$$L(\theta) = -K(p_{\star}||p_{\theta}) - H(p_{\star}). \tag{6}$$

Note that this conclusion is reached without assuming an exact model i.e. it is not assumed that  $p_{\star}=p_{\theta_{\star}}$  for some  $\theta_{\star}\in\Theta$ .

This result applies to source separation as follows. The distribution  $p_{\star}$  is the true distribution of  $\mathbf{x}$  *i.e.* the distribution of vector  $A_{\star}\mathbf{s}$ ; the parameter of the parametric model  $\mathcal{P}$  is the unknown mixing matrix:  $\theta = A$ ; the parameter set  $\Theta$  is the set of all invertible  $n \times n$  matrices; the p.d.f.'s in  $\mathcal{P}$  are the distributions of vector  $A\tilde{\mathbf{s}}$  where the source vector is assumed to be distributed as  $\tilde{\mathbf{s}}$  *i.e.* according to distribution (4).

In this setting, eq. (6) becomes  $L(A) = -K(A_{\star}\mathbf{s}||A\tilde{\mathbf{s}}) - H(A_{\star}\mathbf{s})$ : the contrast function associated with the likelihood appears to be

$$\phi_L(A) \stackrel{\text{def}}{=} -K(A_{\star}\mathbf{s}||A\tilde{\mathbf{s}}) \tag{7}$$

because  $H(A_{\star}\mathbf{s})$  being an additive constant (not depending on the parameter A) can be discarded.

### III. DISCUSSION

In view of (5) and (7), the function  $\phi: \mathbb{R}^{n \times n} \mapsto \mathbb{R}$ 

$$\phi(C) \stackrel{\text{def}}{=} -K(C\mathbf{s}||\tilde{\mathbf{s}}) \tag{8}$$

appears to play a central role. Indeed, we can write

$$\phi_I(B) = \phi(BA_{\star}) \qquad \phi_L(A) = \phi(A^{-1}A_{\star}).$$

The first equality stems from (5) and  $B\mathbf{x} = BA_{\star}\mathbf{s}$ . The second equality is by applying property (13) to eq. (7) with  $\mathbf{f}(\mathbf{u}) = A^{-1}\mathbf{u}$ .

Hence, it is found that the contrasts associated with infomax and with maximum likelihood coincide provided B is identified to  $A^{-1}$ . Interpretation is straightforward in either case: contrast optimization corresponds to a 'Kullback matching' between the hypothesized source distribution  $\tilde{\mathbf{s}}$  and the distribution of  $C\mathbf{s}$  where C is either  $BA_{\star}$  or  $A^{-1}A_{\star}$ .

With the correct source model, i.e. when  $\tilde{\mathbf{s}}$  is distributed as  $\mathbf{s}$ , the contrast reduces to  $\phi(C) = -K(C\mathbf{s}||\mathbf{s})$ . This is maximized at C = I because  $K(\mathbf{s}||\mathbf{s}) = 0$  which is the lowest possible value, the KL divergence being non negative.

What happens with a wrong source model or — equivalently— when the squashing functions are *not* the c.d.f.'s of the source distributions? We sketch an answer, based on the following functions:

$$f_i(s) \stackrel{\text{def}}{=} -\frac{q_i'(s)}{q_i(s)} = -\frac{d \log q_i(s)}{ds} \qquad 1 \le i \le n.$$

The stationary points of the likelihood/infomax contrast cancel the the gradient of  $\phi$ . Differentiating  $\phi$ , it is easily found that these are the matrices C such that  $\mathbf{y} = C\mathbf{s}$  verifies

$$\mathbf{E}f_i(y_i)y_j = \delta_{ij} \qquad 1 \le i, j \le n, \tag{9}$$

 $\delta_{ij} = 1$  if i = j and 0 otherwise. Let  $\lambda_i$  be a solution of

$$E\{f_i(\lambda_i s_i)\lambda_i s_i\} = 1 \qquad 1 \le i \le n.$$
 (10)

Then, matrix  $C = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$  is a stationary point of  $\phi(C)$  if the source signals have zero mean: Es = 0. This is easily seen because the stationarity condition (9) is satisfied for i = j thanks to (10) and for  $i \neq j$  due to

$$E\{f_i(\lambda_i s_i)\lambda_j s_i\} = E\{f_i(\lambda_i s_i)\} E\{\lambda_j s_i\} = 0.$$

The first equality is by independence of the source signals; the second one by the zero-mean condition. For a wrong source model:  $q_i \neq r_i$ , one generally has  $\lambda_i \neq 1$  and thus  $C = \operatorname{diag}(\lambda_1, \ldots, \lambda_n) \neq I$ . However, such a C still is a satisfactory solution with respect to source separation since source signals are recovered up to scaling factors. Unfortunately, one cannot conclude that the likelihood/infomax contrast is completely 'robust' to misspecifying source distributions because too large a mismatch may turn  $C = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$  into an unstable stationary point, as observed in [1].

## Conclusion

The infomax principle was shown to coincide with the maximum likelihood principle in the case of source separation. Both principles explicitly or implicitly assume given source distributions. They consist in minimizing the Kullback divergence between the distribution at the output of a separating matrix and the hypothesized source distribution. It thus appears important to match source distributions as closely as possible as already noted in [1] and as is obvious from the ML standpoint. Even with a wrong source model, a stationary point of the contrast is still obtained for separated (but generally scaled) signals even though the stability cannot be guaranteed for too large a mismatch. Both principles also hint at a more general approach involving joint estimation of the mixing matrix and of (some characteristics of) source distributions. First steps in this direction are taken in [1]; an elegant and well developed approach is to be found in [5].

APPENDIX: INFORMATION THEORETIC QUANTITIES.

• The differential entropy of a variable with p.d.f. p is denoted H(p); the Kullback-Leibler divergence between two p.d.f.s p and q is denoted K(p||q). Definitions are

$$H(p) = -\int_{\mathbf{V}} \log(p(\mathbf{y})) \ p(\mathbf{y}) \ d\mathbf{y}$$
 (11)

$$K(p||q) = \int_{\mathbf{y}} \log \left(\frac{p(\mathbf{y})}{q(\mathbf{y})}\right) p(\mathbf{y}) d\mathbf{y}.$$
 (12)

whenever the integrals exist. A convenient abuse of notation is

$$H(\mathbf{y}) = H(p)$$
  $K(\mathbf{y}||\mathbf{z}) = K(p||q)$ 

if p (resp. q) is the density of a random vector  $\mathbf{y}$  (resp.  $\mathbf{z}$ ).

- $K(p||q) \ge 0$  with equality iff p and q agree p-almost everywhere.
- The KL divergence is invariant under an invertible transformation  $\mathbf{f}$  of the sample space:

$$K(\mathbf{f}(\mathbf{u})||\mathbf{f}(\mathbf{v})) = K(\mathbf{u}||\mathbf{v}) = K(\mathbf{f}^{-1}(\mathbf{u})||\mathbf{f}^{-1}(\mathbf{v})).$$
(13)

• The differential entropy of a distribution with support  $(0,1)^n$  also is the KL divergence between this distribution and the uniform distribution **u** on  $(0,1)^n$ . Clearly:

$$H(\mathbf{z}) = -\int p_{\mathbf{z}}(\mathbf{z}) \log \left( \frac{p_{\mathbf{z}}(\mathbf{z})}{\prod_{i=1}^{n} \mathbf{1}_{(0,1)}(z_i)} \right) d\mathbf{z} = -K(\mathbf{z}||\mathbf{u}|).$$
